(57) **ABSTRACT**

A sensor assembly comprises a base plate and a sensor member displaceable relative to the base plate. A spring arrangement operates in first and second stages in response to displacement of the sensor member relative to the base plate. Different resolutions of force and torque measurements are associated with the first and second stages. A light sensitive transducer senses displacement of the sensor member relative to the base plate and generates corresponding output signals. A collimator directs a plurality of light beams onto the light sensitive transducer so that the light beams strike different pixels of the light sensitive transducer to sense displacement of the sensor member relative to the base plate.

SENSOR ASSEMBLY AND METHOD FOR MEASURING FORCES AND TORQUES

RELATED APPLICATIONS

This application claims priority to and the benefit of U.S. Provisional Patent Application No. 61/777,596, filed on Mar. 12, 2013, the entire contents of which are hereby incorporated by reference.

TECHNICAL FIELD

The disclosure relates generally to a force/torque sensor assembly and a method for measuring forces and torques. In some embodiments, the force/torque sensor assembly and method are employed in a robotic system comprising an instrument and a manipulator used to position the instrument.

BACKGROUND

Medical practitioners have found it useful to use robotic systems to assist in the performance of surgical procedures. Such robotic systems typically include a manipulator having a moveable arm comprising one or more links. A surgical instrument is attached to a free end of the arm. The instrument is designed to be applied to a surgical site. A controller regulates movement of the arm to position the instrument with a high degree of accuracy at the surgical site.

A component of many robotic systems is a force/torque sensor assembly. The force/torque sensor assembly is attached between the free end of the arm and the instrument. The force/torque sensor assembly monitors forces and torques that are applied to the instrument. These may be forces and torques that are applied to the instrument as a consequence of the instrument pressing against tissue. These also may be forces and torques a practitioner applies in order to set a position and/or orientation of the instrument. Signals output by the force/torque sensor assembly are received by the controller. The controller uses these signals to determine a target position for the instrument. Based on the determined target position, the controller actuates the arm in order to advance the arm so that the instrument is moved to the target position.

In order to ensure all forces and torques applied to the instrument are measured, it is common practice to provide a six component force/torque sensor assembly. This type of force/torque sensor assembly measures forces applied to the instrument along three axes and torques applied to the instrument around the three axes.

One type of six component force/torque sensor assembly comprises a set of strain gauges. These gauges include a static member to which a plurality of beams are flexibly mounted. Typically one or more strain gauges are associated with each beam. Each strain gauge acts as a transducer that is used to convert a force or torque into an electrical signal. Each strain gauge generates an electrical signal proportional to the flexure of the beam with which the strain gauge is associated. The output signals from the strain gauges are input variables into an algorithm that yields the measured forces and torques.

In force/torque sensor assemblies employing strain gauges, thermal drift is a common problem. Thermal drift occurs when a change in temperature causes a contraction or expansion of parts. Thermal drift can result in inaccurate placement of the instrument at the surgical site. It is also common for these types of force/torque sensor assemblies to take force and torque measurements at a single resolution. In

2

some cases it may be desirable for the force/torque sensor assembly to be capable of measuring forces and torques at multiple resolutions.

Thus, there is a need in the art for a force/torque sensor assembly and method of measuring forces and torques that overcomes one or more of these deficiencies.

SUMMARY

In one embodiment a sensor assembly is provided. The sensor assembly comprises a base plate and a sensor member displaceable relative to the base plate. A spring arrangement operates in first and second stages in response to displacement of the sensor member relative to the base plate. Different resolutions of force and torque measurements are associated with the first and second stages. A light sensitive transducer senses displacement of the sensor member relative to the base plate and generates corresponding output signals.

In another embodiment a sensor assembly is provided that comprises a light sensitive transducer having a plurality of pixels. A light source provides light to be directed in a plurality of light beams onto the light sensitive transducer so that the light beams strike different pixels of the light sensitive transducer to sense displacement of a sensor member relative to a base plate.

In yet another embodiment, a method is provided for assessing forces and torques using a sensor including a light sensitive transducer having a plurality of pixels. The method comprises operating the sensor to direct a plurality of light beams onto the light sensitive transducer. A load is applied on the sensor so that each of the plurality of light beams move on the light sensitive transducer. Forces and torques are determined based on differences in locations of pixels lighted by the light beams as the light beams move in response to the applied load.

Robotic systems and methods employing these sensor assemblies and methods for assessing forces and torques are also provided.

One advantage of these sensor assemblies and methods is that the sensor assemblies are capable of determining forces and torques at different resolutions for certain applications. Another advantage is that the sensor assemblies operate optically to avoid potential thermal drift issues associated with strain gauges.

BRIEF DESCRIPTION OF THE DRAWINGS

Advantages of the present invention will be readily appreciated as the same becomes better understood by reference to the following detailed description when considered in connection with the accompanying drawings wherein:

FIG. 1 is an overview of a robotic system including a manipulator used to position and advance a surgical instrument on a patient;

FIG. 2 is a side view of a force/torque sensor assembly to which the surgical instrument, an instrument mount, and a mounting plate are attached;

FIG. 3 is a side view of the force/torque sensor assembly seated between an arm of the manipulator and mounting plate, the force/torque sensor assembly including a head plate, a diverter plate with an inner and outer hub, and a base plate;

FIG. 4 is an exploded perspective view of the force/torque sensor assembly;

FIG. 5 is a plan view of a diverter plate of the force/torque sensor assembly;

3

FIG. 5A is a graph showing two stages of sensitivity of the force/torque sensor assembly;

FIG. 6 is an exploded perspective view of pins in a pin housing;

FIG. 7 is a side view illustrating the pins in the pin housing;

FIG. 8 is a plan view of the diverter plate with the pins located in serpentine springs of the diverter plate;

FIG. 9 is a partial cross-sectional view through the pins in the serpentine spring;

FIG. 10 is a plan view of the base plate;

FIG. 11 is a plan view of a collimator of the force/torque sensor assembly;

FIG. 11A is a plan view of a light sensitive transducer illustrating separate sectors associated with separate light beams;

FIG. 12A is a cross-sectional view illustrating the collimator with a plurality of normal bores extending through the collimator;

FIG. 12B is a cross-sectional view illustrating the collimator with the plurality of normal bores in a different orientation than FIG. 12A;

FIG. 13A is a cross-sectional view illustrating the collimator with a plurality of angled bores extending through the collimator;

FIG. 13B is a cross-sectional view illustrating the collimator with the plurality of angled bores in a different orientation than FIG. 13A;

FIG. 14A is a plan view of the light sensitive transducer of the force/torque sensor assembly illustrating where light beams strike the light sensitive transducer at a start of a time frame;

FIG. 14B is a plan view of the light sensitive transducer illustrating where light beams strike the light sensitive transducer at an end of the time frame;

FIG. 15 is a plan view of the light sensitive transducer showing locations of centroids of lights beams;

FIGS. 15A and 15B are graphs illustrating changes in signal intensity along pixel columns and rows, respectively, used to determine the centroids of the light beams illustrated in FIG. 15;

FIG. 16 is an illustration of the correlation between movement of light beams on the light sensitive transducer with three torques T_x , T_y , and T_z , and three forces F_x , F_y , and F_z ;

FIG. 17 is a schematic view of the instrument, bur, and force/torque sensor assembly showing a distance R from a centroid of the bur to a center of the force/torque sensor assembly;

FIGS. 18A-18C are flow diagrams illustrating steps carried out by methods of sensing forces and torques

FIG. 19 is a schematic illustration of the collimator and changes in where one light beam strikes the light sensitive transducer between the start of the time frame and the end of the time frame;

FIG. 20 is a plan view of an alternative collimator;

FIG. 21 is a perspective view of the alternative collimator of FIG. 20;

FIG. 22 is a plan view of an alternative embodiment of the diverter plate in which pins are vertically seated within serpentine springs;

FIG. 23 is a plan view of a second alternative embodiment of the diverter plate; and

FIG. 24 is a plan view of a third alternative embodiment of the diverter plate.

DETAILED DESCRIPTION

I. Overview

FIG. 1 illustrates a robotic surgical system including a manipulator 30 and a surgical instrument 32. The surgical

4

instrument 32 is supported by the manipulator 30 for movement with respect to a patient P. In some embodiments, the manipulator 30 functions in manual and semi-autonomous modes to position the instrument 32 with respect to a target site on the patient P.

The manipulator 30 includes an instrument mount 36 to which the instrument 32 is rigidly attached. In some embodiments, the instrument 32 is also removably attached to the instrument mount 36. Manipulator 30 moves the instrument mount 36 to position and orient the instrument 32 so that the instrument 32 performs the intended medical/surgical procedure on the patient P.

A surgical navigation system 220 monitors the position and/or orientation of the instrument 32 relative to the target site. The surgical navigation system 220 communicates position and/or orientation data to the manipulator 30 so that the manipulator 30 can properly position the instrument 32.

Manipulator 30 includes a mobile cart 38. A linkage assembly 40 moveably connects the instrument 32 to the cart 38. In the illustrated embodiment this linkage assembly 40 comprises first and second parallel four bar link assemblies 42, 44. The position of each joint of each link assembly is set by a plurality of actuators 46. In FIG. 1, one of the actuators 46 associated with link assembly 42 is identified.

A manipulator controller 48, (partially shown as a phantom box in FIG. 1) is mounted to the cart 38. The manipulator controller 48 transmits the control signals that cause the actuators 46 to appropriately set the links of the link assemblies 42, 44. The manipulator controller 48 sets the positions of the links based on a number of input signals. These input signals include signals from the surgical navigation system 220.

The structure of the manipulator 30, including the manipulator controller 48, and the instrument 32 are set forth in more detail in U.S. patent application Ser. No. 13/958,070, filed Aug. 2, 2013, entitled, "Surgical Manipulator Capable of Controlling a Surgical Instrument in Multiple Modes," the disclosure of which is hereby incorporated by reference.

In some embodiments the instrument 32 includes a power generating unit (not shown). The power generating unit converts electrical signals into a form of energy that is applied to the patient P. This energy may be mechanical, sonic, thermal, RF, EM or photonic. When the instrument 32 includes a power generating unit, the energy is applied to the target site through an energy applicator 50. In the illustrated embodiment, the instrument 32 includes an energy applicator 50 in the form of a cutting bur for cutting tissue such as bone. The bur extends from a handpiece of the instrument 32.

II. Force/Torque Sensor Assembly

As shown in FIG. 2, a force/torque sensor assembly 52 is provided to react to loads applied to the instrument 32. The loads may include resistive forces and torques to which the instrument 32 is exposed as a result of the instrument 32 being pressed against tissue. The loads may also include forces and torques applied to the instrument 32 by a user when the user desires to set a position and/or orientation of the instrument 32. Manipulator controller 48 sets the position of the links, and thus the instrument 32, based on the forces and torques measured by the force/torque sensor assembly 52.

The force/torque sensor assembly 52, as shown in FIGS. 3 and 4, acts between the linkage assembly 40 and the instrument 32. The force/torque sensor assembly includes a head plate 54, a diverter plate 56 and a base plate 58. These plates 54, 56, 58 support the force/torque sensor assembly 52 for operation between the linkage assembly 40 and the instru-

5

ment 32. In FIG. 3, the widths of the plates 54, 56 and 58 are exaggerated for purposes of illustration.

Referring to FIG. 4, the head plate 54 is disc shaped so as to have opposed proximally and distally directed faces that are planar and parallel to each other. Head plate 54 is formed from a single piece of stainless steel or other metal alloy. Head plate 54 has a thickness of approximately 6.5 mm. In some embodiments, head plate 54 has a diameter of between about 4.5 and 6.5 mm. Head plate 54 is attached to a proximally directed face of a mounting plate 60. The mounting plate 60 is fixed to the instrument mount 36. (Here “proximal” is understood to be towards the manipulator cart 38, away from the target site to which the instrument 32 is to be applied and “distal” is understood to be away from manipulator cart 38, towards the target site to which the instrument 32 is to be applied).

Sets of first and second throughbores 62, 64 extend between the opposed faces of the head plate 54. The first throughbores 62 are located radially outward from the center of the head plate 54. The first throughbores 62 are equally spaced from each other. A proximal opening of first throughbores 62 is defined by a tapered recess 66 that is angled inwardly toward the center of first throughbores 62. Second throughbores 64 are spaced radially outwardly from first throughbores 62 so as to be located a small distance inwardly from an outer perimeter of head plate 54. The second throughbores 64 are also equally spaced from each other, yet not radially aligned with the adjacent first throughbore 62. Head plate 54 is further formed to define a side bore 68 that extends radially inwardly from a side surface of the head plate 54. Threaded fasteners (not shown) extend through second throughbores 64 to hold the head plate 54 to the mounting plate 60.

Diverter plate 56 is located between the head plate 54 and the base plate 58. Diverter plate 56 includes inner and outer sensor members. In the embodiment shown, the inner and outer sensor members are inner and outer hubs, 70 and 72, respectively. Inner hub 70 extends distally forward of the outer hub 72. Inner hub 70 is connected to and able to move relative to the outer hub 72. Outer hub 72 is statically secured to base plate 58. The inner hub 70 is statically secured to head plate 54. The hubs 70, 72 are both formed out of a single piece of hardened stainless steel.

Inner hub 70 has a generally circular outer shape. Inner hub 70 is disposed within the outer hub 72. An outer perimeter of the inner hub 70 is defined, in part, by three flat surfaces 74 that are arcuately and equally spaced from each other. A curved surface 76 is located between each adjacent pair of flat surfaces 74.

Tines 78 extend radially outwardly from each curved surface 76. Tines 78 are equiangularly spaced apart from each other and extend from the centers of curved surfaces 76. Along the axes that extend between the opposed proximally and distally directed faces of the tines 78, the tines 78 have a depth that is from about 0.25 mm to about 1.0 mm less than the depth of inner hub 70. The proximal faces (not numbered) of the tines 78 are flush with the proximal face of the inner hub 70. The distally directed faces (not numbered) of the tines are thus recessed relative to the adjacent distally directed face of inner hub 70.

Three hub throughbores 80 are located a short distance inward from the outer perimeter of inner hub 70. Hub throughbores 80 have openings with a diameter approximately equal to the diameter of first throughbores 62 in head plate 54. Each hub throughbore 80 aligns with a separate first throughbore 62. Inner hub 70 has a centrally located central throughbore 82. Central throughbore 82 is larger in diameter

6

than hub throughbores 80. A cylindrical step 84 projects radially from an inner surface that defines the central throughbore 82. Step 84 is recessed proximally away from the distal face of the inner hub 70. Step 84 extends inwardly approximately 0.75 mm from the inner surface of central throughbore 82. A groove 86 extends radially outwardly from central throughbore 82. Groove 86 is recessed relative to the distal face of inner hub 70. The base of groove 86 is coplanar with step 84.

As shown in FIG. 5, outer hub 72 is generally ring-like in shape. Outer hub 72 has a diameter approximately equal to that of head plate 54. The outer hub 72 has the same proximal face-to-distal face depth as the tines 78. Thus the depth of the outer hub 72 is less than that of inner hub 70. The distal face of inner hub 70 is raised above the distal face of outer hub 72, as seen in FIG. 3. In FIG. 3, the extent to which the inner hub 70 projects forward from the outer hub 72 is exaggerated for purposes of illustration.

Outer hub 72 has three inwardly directed tabs 88. Tabs 88 are equiangularly spaced apart from each other. Each tab 88 has side surfaces 90 that taper inwardly towards each other. Each tab 88 has an arcuately shaped inner surface 92. Inner surfaces 92 extend around a common circle that is concentric with the center axis of outer hub 72. Each tab 88 is bisected by a tine slot 94. Each tine slot 94 extends radially outwardly from the inner surface 92. Each tab 88 also has a tab throughbore 96. Tab throughbores 96 are spaced circumferentially apart along the outer hub 72. Outer hub 72 is further shaped so that there is planar inner surface, a flat 98, between each adjacent pair of tabs 88.

Each tine 78 extends into a separate one of the tine slots 94. Tine slots 94 have a width that is approximately 0.1 mm to 0.75 mm greater than the width of tines 78. Diverter plate 56 is further dimensioned so that when the outer hub 72 is in the neutral position, the outer end of each tine 78 is spaced approximately 0.1 mm to 0.75 mm from the adjacent inwardly directed surfaces of the tab 88 that defines the associated tine slot 94.

As seen in FIGS. 4 and 5, a spring arrangement movably attaches the inner hub 70 to the outer hub 72. The spring arrangement includes three spring devices 102. Each spring device 102 extends outwardly from a separate one of the flat surfaces 74. Each spring device 102 includes a serpentine spring 104 and a leaf spring 106 arranged in series.

Each serpentine spring 104 includes a head 108, a torso 110 and a leg 112. The head 108 is the portion of the serpentine spring 104 connected to the inner hub 70. The head 108 projects radially outwardly from the flat surface 74.

The torso 110 extends from the head 108. Each torso includes a plurality of U-shaped folds 114 and pleats 116 extending from the U-shaped folds 114. In one embodiment, the torso 110 is formed from plural pleats 116 and folds 114. The pleats 116 are parallel to each other. Folds 114 are generally semi-circular in shape. A first one of the folds 114 connects one pleat 116 to the head 108. A second one of the folds 114 connects two pleats 116 together. A third one of the folds 114 connects another pleat 116 to the leg 112. Folds 114 are flexible. The flexibility of the folds 114 allows the longitudinal axes of the pleats 116 to shift positions.

Each leg 112 comprises a relatively thick base. This base of the leg 112 is the portion of the leg 112 from which the adjacent fold 114 extends. Two feet 118 extend outwardly from the outer end of each leg 112. Each foot 118 is in the form of a thin strip having a thickness of approximately 0.25 to 0.75 mm. The feet 118 forming a pair of feet 118 are coplanar. Each foot 118 has an end that merges into the side surface of an adjacent tab 88. The feet 118 merge into the tabs

88 at locations inwardly radially from the flats **98**. Thus, each pair of feet **118** is parallel with and spaced inwardly from the adjacent flat **98**. In some embodiments, this spacing is between approximately 0.25 mm and 0.75 mm. Given that feet **118** are formed from flexible material and the feet **118** of each pair of feet **118** are coplanar, each pair of feet **118** defines one of the leaf springs **106**.

Each spring device **102** can thus be considered to be a plural stage spring device. One spring stage is the serpentine spring **104** formed by folds **114** and pleats **116**. The second spring stage is the leaf spring **106** formed by feet **118**. FIG. 5A illustrates how these first and second stages affect the resolution of force/torque measurements enabled by the force/torque sensor assembly **52**.

Referring to FIGS. 6-9, each serpentine spring **104** accommodates a plurality of pins **120**. Each pin **120** is generally cylindrical in shape. Each pin **120** is comprised of hardened stainless steel. Each pin **120** has a length such that the pin **120** can extend across the entire width of the adjacent torso **110**. The pins **120** have a radius that is approximately 0.625 mm to 2.5 mm less than the radius of circles defined by the adjacent folds **114**. In one embodiment, pins **120** are approximately 6.25 mm in length and 1.168 mm in diameter. A first one of the pins **120** extends between the head **108** and the adjacent pleat **116**. A second of the pins **120** is located between the two pleats **116**. A third of the pins **120** is located between the radially outermost pleat **116** and the leg **112**.

Each set of three pins **120** is seated in a pin housing **122**. Pin housing **122** is comprised of a cap **124** and a pin housing base **126**. Pins **120** are positioned between the cap **124** and the pin housing base **126**. Cap **124** includes a panel **128**, and two opposed side walls **130**. Panel **128** is rectangular in shape. Each side wall **130** extends downward from side edges of panel **128**. A panel bore **132** extends through the center of panel **128**. Pin housing base **126** is generally block-like in shape. A base groove **134** extends through the middle of pin housing base **126**. Base groove **134** is dimensioned to accept torso **110**. A pin groove **136** extends through the center of pin housing base **126**. Pin groove **136** intersects and is perpendicular to the base groove **134**. The pin groove **136** is of shallower depth than the base groove **134**.

Referring to FIGS. 4 and 10, base plate **58** is attached to a distal end component **138** of the linkage assembly **40** of the manipulator **30**. This component **138** may be a coupler, robot flange, wrist or other component. The base plate **58** is formed from hardened stainless steel. Base plate **58** is generally disc like in shape and has an outer diameter equal to that of the outer diameter of outer hub **72**. The base plate **58** has an inner circular section **140** and an outer rim **142**. Rim **142** extends circumferentially around the outer edge of circular section **140**. Rim **142** has a distally directed top face that is raised above and parallel with the distally directed face of inner circular section **140**. Rim **142** is formed to have a plurality of first openings **144** and second openings **146** that extend between the opposed proximally and distally directed faces of the rim **142**. There are three first openings **144** that are equiangularly spaced apart from each other. There are three second openings **146** that are equiangularly spaced apart from each other.

A plurality of recesses **148** are located on the distal face of rim **142**. The recesses **148** are open along the inner surface of rim **142**. Each recess **148** is generally in the form of a rectangle. Each recess **148** is defined by a pair of opposed side surfaces and a bottom surface. Each recess **148** is shaped so the distance across the opposed side surfaces are equal to the width across tine slots **94**. Three recesses **148** are equally spaced apart on the distal face of rim **142**. The recesses **148**

are positioned so that when force/torque sensor assembly **52** is assembled, each recess **148** is in registration with one of the tine slots **94** in the diverter plate **56**.

Fasteners (not shown) extend through the first openings **144** to hold the base plate **58** to the distal end component **138** of the linkage assembly **40**. Fasteners (not shown) extend through the second openings **146** and tab throughbores **96** to hold the diverter plate **56** to the base plate **58**.

The force/torque sensor assembly **52** is an optically-based sensor assembly that includes a light source **154** mounted to the base plate **58**. Light from the light source **154** is directed through a collimator **156** onto a light sensitive transducer **158**. The collimator **156** converts the light into a plurality of light beams. As loads are applied on the instrument **32**, the collimator **156** is displaced relative to the light sensitive transducer **158** so that the light beams strike different pixels of the light sensitive transducer **158**. This movement of the light beams effectively senses the forces and torques applied to the instrument **32** and can be correlated into force and torque measurements.

The light source **142** is located adjacent to the outer edge of the distal face of inner circular section **140**. Light source **142** is thus adjacent and may be coplanar with the inwardly directed face of rim **142**. In some embodiments, light source **142** is an LED light source that includes one or more light emitting diodes (LEDs). Two LEDs are shown in FIG. 4.

A light pipe **160** is mounted to a distal face of inner hub **70**. The light pipe **160** receives light emitted by the light source **142** and directs it to the collimator **156**. Light pipe **160** is shaped to have a cylindrical stem **162**. The proximal end of the stem **162** is located above light source **142** to receive light emitted from the light source **142**. A branch **164** extends perpendicularly from a distal end of stem **162**. Branch **164** is dimensioned to seat in inner hub groove **86**. A circular head **166** extends from a free end of the branch **164**. Head **166** is formed to have a disc shaped lens. Head **166** is dimensioned to seat in a counterbore to central throughbore **82**. Upon assembly of the force/torque sensor assembly **52**, the light pipe **160** is positioned so that the head **166** is disposed in the counterbore above the collimator **156**.

The light pipe **160** is formed of plastic, glass or other material that is able to convey light emitted by light source **142** to the collimator **156**. In some embodiments, the light pipe **160** is a fiber optic conduit or an injection molded light pipe comprised of a single piece of plastic. In other embodiments the light pipe **160** is eliminated altogether and the LEDs are instead positioned directly above the collimator **156** or other light focusing device.

Collimator **156** is fixed to the inner hub **70**. The collimator **156** may be fixed by adhesive, tape, welding or other methods. Collimator **156** is seated in the counterbore beneath the light pipe **160**. Collimator **156** is disc shaped and has a diameter approximately equal to counterbore so that the outer perimeter of collimator **156** seats on step **84** formed in inner hub **70**. In one embodiment collimator **156** has a diameter of approximately 7.5 mm. The collimator **156** is formed from quartz or alternatively is built into the diverter plate **56** (e.g., machined to be a part of the diverter plate **56**).

As seen in FIG. 11, collimator **156** is formed to have a plurality of light openings. Four of the light openings are shown as normal bores **172**, **174**, **176**, **178**. Normal bores **172**, **174**, **176**, **178** are throughbores formed normally to opposed top and bottom surfaces of the collimator **156**, i.e., normal bores **172**, **174**, **176**, **178** extend through collimator **156** along axes perpendicular to the opposed top and bottom surfaces of

the collimator **156**. The normal bores **172, 174, 176, 178** are arranged in a square pattern and spaced equidistantly from a center of collimator **156**.

The plurality of light openings also include two angled bores **180, 182**, as seen in FIGS. **11, 13A** and **13B**. Angled bores **180, 182** are angled in that they extend through the collimator **156** along axes that are arranged at an acute angle to the normal axes between the top and bottom surfaces of the collimator **156**. Angled bores **180, 182** are spaced equally away from the center of the collimator **156**. Angled bores **180, 182** angle inwardly towards the center of collimator **156**. In some embodiments, bores **172, 174, 176, 178, 180, 182** are square-shaped. In other embodiments, bores **172, 174, 176, 178, 180, 182** are circular in shape.

The light sensitive transducer **158** is located centrally on a printed circuit board **184**. The printed circuit board **184** is seated on the distally directed face of circular section **140** and is thereby fixed with respect to the base plate **58**. The printed circuit board **184** has a shape and size approximately equal to that of the distal face of circular section **140**. In the illustrated embodiment, the light sensitive transducer **158** is an image sensor. The image sensor may be a CMOS image sensor or any other light sensitive transducer. In one version the image sensor is the LUPA 1300A sensor available from Cypress Semiconductor of San Jose, Calif.

The light sensitive transducer **158** contains a number of individual light sensitive elements such as pixels. The pixels are arranged in a row-by-column format or matrix. Each pixel outputs a signal representative of the strength of the light striking the pixel. In some embodiments, light sensitive transducer **158** has a pixel size of 25 microns or less. In certain embodiments, the light sensitive transducer **158** has a resolution of 1280×1024 pixels. Each pixel is approximately 14 microns by 14 microns in this embodiment.

A voltage regulator **186** is mounted to printed circuit board **184**. Voltage regulator **186** supplies a constant voltage signal to light sensitive transducer **158**. In the illustrated embodiment light sensitive transducer **158** is shown mounted to an exposed face of voltage regulator **186**.

The bores **172, 174, 176, 178, 180, 182** of the collimator **156** divide the light from the light pipe **160** into a number of separate light beams. The light beams strike a face of the light sensitive transducer **158**. Light sensitive transducer **158** outputs signals representative of the locations that the light beams strike on the light sensitive transducer **158**. These signals may be sent to a local controller (not shown) for processing. The signals are processed to ultimately yield forces and torques. The manipulator controller **48** utilizes the forces and torques to control movement of the actuators **46** and, thus, the instrument **32**. It should be appreciated that the output signals from the light sensitive transducer **158** could also be sent directly to the manipulator controller **48** in other embodiments.

During surgery, loads applied to the instrument **32** cause at least miniscule displacement of the instrument **32**. This displacement of the instrument **32** is transmitted through the instrument mount **36** and the mounting plate **60** to the head plate **54** and inner hub **70**—all being considered a single rigid body. The displacement of the inner hub **70** results in a shift of the position and/or orientation, i.e., movement, of the collimator **156** relative to the light sensitive transducer **158**. As a result, the light beams from the bores **172, 174, 176, 178, 180, 182** also move thereby enabling the determination of forces and torques.

III. Determining Forces and Torques

Force/torque sensor assembly **52** is considered to be in a loaded state when loads are applied to the instrument **32**.

When loads (e.g., forces and/or torques) are applied to the force/torque sensor assembly **52**, the inner hub **70** can engage in six types of movement relative to the outer hub **72**. Three of the movements are translation. The inner hub **70** can move along the x-axis, arbitrarily, the horizontal axis through the inner hub **70** in FIG. **5**. Inner hub **70** can engage in movement along the y-axis, arbitrarily the vertical axis through the inner hub **70** in FIG. **5**. The inner hub can engage in movement along the z-axis, arbitrarily the axis through the center of the inner hub **70** that extends in and out of the plane of FIG. **5**. Inner hub **70** can also engage in at least some rotational movement around each of the above-identified axes. Typically as a result of the application of forces and torques to the force/torque sensor assembly **52**, the inner hub **70** engages in several of these movements.

When there is an application of force and/or torque to the instrument **32**, the collimator **156** and light pipe **160**, consequently, equally move with the inner hub **70**. This displacement of the collimator **156** causes light emitted by the light source **154** to strike different pixels of the light sensitive transducer **158**. The light sensitive transducer **158** outputs signals that show the movements of the collimated light which is directly related to the forces and torques applied to the instrument **32**.

In the absence of the application of any forces or torques to the force/torque sensor assembly **52**, the force/torque sensor assembly **52** is considered in the unloaded state. When the manipulator **30** is in use, even in the absence of other forces, gravity imposes forces and torques on the force/torque sensor assembly **52**. It should be understood that a major component of this gravitation force is the force gravity places on the instrument **32** and energy applicator **50**. This gravitational force causes some displacement of the inner hub **70** relative to the outer hub **72** when inner hub **70** is in the pure unloaded state. Given the nominal nature of this force, and nominal displacement of the inner hub **70**, the locations of the light beams are considered to be in their gravity-offset unloaded state.

During operation of manipulator **30**, the light emitted by the light source **154** (represented by numeral **155** in the Figures) extends through bores **172, 174, 176, 178, 180, 182** as light beams. These light beams strike different clusters of pixels on the surface of the light sensitive transducer **158**. More specifically, each light beam strikes a different cluster of pixels in the unloaded state and in the loaded state. The shifts in the positions/locations of the clusters of pixels from the unloaded state to the loaded state, e.g., from a start of a time frame (initial cluster) to an end of the time frame (final cluster), are used to determine the forces and torques.

FIGS. **12A** and **12B** depict two of the light beams that pass through two of the normal bores, bores **172** and **176** in the unloaded and loaded states. FIGS. **13A** and **13B** depict how two light beams pass through the angled bores **180, 182** in the unloaded and loaded states. Notably, the light beams that pass through the angled bores **180, 182** strike the light sensitive transducer **158** as ellipses.

During manufacture, the collimator **156** is arranged with respect to the light sensitive transducer **158** so that for the maximum range of motion of each light beam (for all six degrees of freedom) each light beam is constrained to separate sectors S (or windows) on the light sensitive transducer **158**, so that the pixels in each sector S can be separately electronically processed to determine a location of a centroid of the light beam on the light sensitive transducer **158**. See, for example, the light beams **172B, 174B, 176B, 178B** shown in FIG. **11A** from normal bores **172, 174, 176, 178** that strike the light sensitive transducer **158** in separate sectors S1-S4 and

11

the light beams **180B**, **182B** from angled bores **180**, **182** that strike the light sensitive transducer **158** in separate sectors **S5-S6**. For the full range of displacement of the force/torque sensor assembly **52**, each of the light beams are constrained to remain fully in their corresponding sectors **S1-S6**.

The light sensitive transducer **158** continually outputs to manipulator controller **48** the signals emitted by each pixel in each sector **S1-S6**. Each pixel has a specific row/column location on the light sensitive transducer **158**. The signals received by manipulator controller **48** are proportional to the quantity of light that strikes the pixel at that location. For purposes of understanding the illustrated embodiment, the pixel at the lower left of FIGS. **14A** and **14B** is considered to be the pixel at row/column location (0, 0) **188**.

As mentioned above, each light beam strikes a cluster of pixels in each sector **S1-S6**. Accordingly, the controller **48** receives from the light sensitive transducer **145** signals that make up an image that includes six sets of pixels, each set comprising output signals from multiple pixels that are exposed to light. For each of these sets of pixels, the controller **48** determines the centroid of the light beams.

The centroids can be determined by processing the signal strengths in each set using conventional processing techniques, as shown in FIGS. **15**, **15A**, and **15B**. For example, the light beams **172B**, **174B**, **176B**, **178B** shown in FIG. **15**, which pass through the normal bores **172**, **174**, **176**, **178**, strike distinct clusters of pixels. These clusters are processed by summing the signal strengths, for each set of pixels associated with sectors **S1-S4**, along all the columns of pixels, and all the rows of pixels, in each sector and identifying the peak signal strengths along the columns and rows to identify the centroid in x, y coordinates. The peak signal strengths may be associated with a specific pixel location, but interpolation or other processing of the summed output signal values may result in the location of the peak signal strengths along the columns and rows not necessarily being bound by physical location of a single pixel. See an example of this processing in FIGS. **15A** and **15B**.

Controller **48** assigns the location of the centroid in the x-y coordinate system of the light sensitive transducer **158** to be on the on-sensor location to which the light beam is applied. Controller **48** performs the above processes six times, once for each light beam and sector. This process is repeated in each frame of operation of the force/torque sensor assembly **52**. Therefore, for each frame of operation, twelve x, y coordinates are provided in the embodiment in which the collimator **156** has four normal bores **172**, **174**, **176**, **178** and two angled bores **180**, **182**. The minimum frequency with which a complete set of signals for all the pixels is output is 1 Hz. In some embodiments, the frequency in which a complete set of signals for all pixels is output is at least 10 Hz or greater. Each set of signals can be considered to represent the positions of the light beams at the end of a single time frame.

It has been shown that in other embodiments fewer coordinates are needed to provide adequate input information to determine the forces and torques. See, for example, the light beams shown in FIG. **16**. Here, only two light beams through two normal bores **216**, **218** are shown along with the two light beams through the two angled bores **180**, **182**. In this case, eight coordinates $x_1, y_1, x_2, y_2, x_3, y_3, x_4, y_4$ are calculated by the controller **48** based on the centroids of the light beams. Still, only six of those coordinates are needed to solve for the forces and torques. These coordinates include $x_1, y_2, x_3, y_3, x_4, y_4$.

The basis for the selection of these coordinates $x_1, y_2, x_3, y_3, x_4, y_4$ comes from understanding how the light beams shift under each of the different force/torque conditions, e.g.,

12

for each of the six forces/torques being determined. These shifts are illustrated in FIG. **16**.

As shown in FIG. **16**, when a force F_x is applied along the x-axis, each of the light beams shift equally along the x-axis, and therefore, F_x can be correlated to a shift in one of the x coordinates of the light beams, such as by a shift in x_1, x_3 , and/or x_4 . Similarly, when a force F_y is applied along the y-axis, each of the light beams shift equally along the y-axis, and therefore, F_y can be correlated to a shift in one of the y coordinates of the light beams, such as by a shift in y_2, y_3 , and/or y_4 .

When a force F_z is applied along the z-axis, the angled nature of the angled bores **180**, **182** yields a change in the positions of their light beams on the light sensitive transducer **158** while the light beams through the normal bores **216**, **218** remain unchanged (e.g., the centroids are unchanged although there may be small changes in the cluster of pixels affected by the light beam). This is a result of displacement of the collimator **156** toward or away from the light sensitive transducer **158** in the z-axis when force F_z is applied. Owing to this displacement, the distance between the two angled light beams on the light sensitive transducer **158** changes. In FIG. **13A**, this distance is depicted as distance $ZADJ^U$. The value of distance $ZADJ^U$ is scalar and constant throughout operation of force/torque sensor assembly **52** as representing the distance in the unloaded state. In FIG. **13B**, $ZADJ^E$ shows how the distance changes in the loaded state. Therefore, since the angled bores **180**, **182** direct their light beams radially inwardly along the x-axis toward the center, F_z can be correlated to a shift in the x coordinates of the light beams through the angled bores, such as by a shift in x_1 and x_3 , as illustrated in FIG. **16**.

When a torque T_x is applied about the x-axis, causing a pivoting of the collimator **156** about the x-axis, each of the light beams shift along the y-axis, but not all equally. As shown in FIG. **16**, when the torque T_x is applied, the shift of the light beam from normal bore **216** along the y-axis is less than the shift from normal bore **218** along the y-axis. The shift of the light beams from the angled bores **180**, **182** along the y-axis falls somewhere in between. The pivoting of the collimator **156** about the x-axis causes one half of the collimator **156** to move closer to the light sensitive transducer **158** and the other half moves away from the light sensitive transducer **158** thereby resulting in different shift distances. As a result, T_x can be correlated to a shift in the y coordinates of the light beams, such as by a shift in y_2, y_3 , and/or y_4 .

Similarly, when a torque T_y is applied about the y-axis, causing a pivoting of the collimator **156** about the y-axis, each of the light beams shift along the x-axis, but not all equally. As shown in FIG. **16**, when the torque T_y is applied, the shift of the light beam from angled bore **180** along the x-axis is less than the shift from angled bore **182** along the x-axis. The shift of the light beams from the normal bores **216**, **218** along the x-axis falls somewhere in between. The pivoting of the collimator **156** about the y-axis causes one half of the collimator **156** to move closer to the light sensitive transducer **158** and the other half moves away from the light sensitive transducer **158** thereby resulting in different shift distances. As a result, T_y can be correlated to a shift in the x coordinates of the light beams, such as by a shift in x_1, x_3 , and/or x_4 .

When a torque T_z is applied about the z-axis, causing a rotation of the collimator **156** about the z-axis, each of the light beams shift equally clockwise or counterclockwise. As a result, T_z can be correlated to a shift in the slope of a line between any two centroids. Thus, for example, T_z can be correlated to the x, y coordinates of any pair of light beams, including x_3, y_3 and x_4, y_4 .

13

Ultimately, the controller **48** is able to compute the three forces F_x , F_y , F_z and the three torques T_x , T_y , T_z applied to the force/torque sensor assembly **52** based on these six coordinates associated with displacement of the centroids of the light beams, e.g., x_1 , y_2 , x_3 , y_3 , x_4 , y_4 . Computation of the forces and torques relies upon a multiple linear regression model and prior calibration of the force/torque sensor assembly **52**.

Calibration of the force/torque sensor assembly **52** includes applying sets of known forces and torques on the force/torque sensor assembly **52**. This includes collecting values for each of the six coordinates x_1 , y_2 , x_3 , y_3 , x_4 , y_4 for each applied force and torque, which yields a plurality of data sets for each of F_x , F_y , F_z , T_x , T_y , T_z . Data arrays of force/torque outputs can then be created for each axis with the outputs zeroed out in the orthogonal axes to constrain the solution. The multiple linear regression is then computed to solve for the row of A values for the particular axis using a least squares method—for example, $Ax = (X^T X)^{-1} X^T F_x$. This computation is conducted for all three axes for force and torque to yield six values in total. Once the force/torque sensor assembly **52** is calibrated, the following calibration matrix can be used to compute the forces and torques (where o is a small offset term):

$$\begin{bmatrix} F_x \\ F_y \\ F_z \\ \tau_x \\ \tau_y \\ \tau_z \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} & a_{15} & a_{16} \\ a_{21} & a_{22} & a_{23} & a_{24} & a_{25} & a_{26} \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} & a_{36} \\ a_{41} & a_{42} & a_{43} & a_{44} & a_{45} & a_{46} \\ a_{51} & a_{52} & a_{53} & a_{54} & a_{55} & a_{56} \\ a_{61} & a_{62} & a_{63} & a_{64} & a_{65} & a_{66} \end{bmatrix} \begin{bmatrix} x_1 \\ y_2 \\ x_3 \\ y_3 \\ x_4 \\ y_4 \end{bmatrix} + \begin{bmatrix} o_1 \\ o_2 \\ o_3 \\ o_4 \\ o_5 \\ o_6 \end{bmatrix}$$

Thus, controller **48** is able to determine the three forces F_x , F_y , F_z and the three torques T_x , T_y , T_z applied to the force/torque sensor assembly **52** using linear algebra and centroid values. These force and torque values are then forwarded to other modules integral with the manipulator controller **48**. These other modules employ the force and torque data to regulate the operation of the manipulator **30**.

Iv. Multi-Stage Resolution

The force/torque sensor assembly **52** provides two stages of sensitivity in a single transducer, as shown in FIG. **5A**. Sensitivity is defined as the resolution of mechanical force/torque data measurements. For example, in one embodiment a first stage captures forces with a minimum and maximum range of zero (0) to five (5) pounds with the maximum upper range being no greater than ten (10) pounds. A second stage captures forces with a minimum and maximum range of five (5) pounds to fifty (50) pounds with the maximum upper range being no greater than one hundred (100) pounds.

Each spring device **102** is dimensioned and configured within the diverter plate **56** to achieve the two levels of sensitivity for determining force and/or torque applied to the instrument **32** thereby providing different resolutions of force/torque measurements.

In one embodiment, when relatively low forces and torques are applied to the force/torque sensor assembly **52**, initially, it is the leaf spring components, i.e., the feet **118**, that flex in the first stage of spring displacement. Folds **114** are not flexed. The flexures of the leaf springs **106** are linearly proportional to the magnitude of composite forces and torques applied to

14

the force/torque sensor assembly **52** and thus provide the first stage of sensitivity of the force/torque sensor assembly **52**, as illustrated in FIG. **5A**.

Once the magnitude of the applied forces and torques reach the maximum of the first stage, at least one pair of feet **118** is flexed outwardly to such an extent that the feet **118** abut the adjacent flat **98** so that further flexure is prevented thereby ending the first stage of spring displacement. The application of still larger forces and torques results in the flexure of the serpentine spring **104** in a second stage of spring displacement. It should be appreciated that when this event occurs one or two of the spring torsos **110** expands, i.e., is placed in tension, while the other torso(s) **110** is placed in compression. Owing to the structure of the spring arrangement, these spring expansions and compressions are again linearly proportional to the magnitude of the composite forces and torques applied to the force/torque sensor assembly **52** and thus provide the second stage of sensitivity of the force/torque assembly **52** shown in FIG. **5A**.

It should be appreciated that the first and second stages of sensitivity are related to the serpentine springs **104** and leaf springs **106** having different spring rates. In some embodiments, the leaf springs **106** could be configured to provide the second stage of sensitivity while the serpentine springs **104** provide the first stage of sensitivity, i.e., by switching which of the serpentine springs **104** or leaf springs **106** have the larger spring rate. In such an embodiment, when one torso **110** is compressed so that all of the pins **120** are fully pinched between elements of the serpentine spring **104**, further flexing of the serpentine spring **104** is stopped thereby ending the first stage of displacement of the serpentine spring **104**. Thereafter, the associated leaf spring **106** is compressed in the second stage of displacement until one or more of the tines **78** bottom out in the tine slots **94** to stop any further displacement.

As previously discussed, the manipulator controller **48** utilizes the forces and torques generated by the force/torque sensor assembly **52** to control movement of the actuators **46** and, thus, the instrument **32**. These two different resolutions of force/torque measurements could be utilized by the manipulator controller **48** for various purposes.

V. Assembly

Force/torque sensor assembly **52** is first assembled by seating the second of the pins **120** within pin groove **136**. The pin housing base **122** is then positioned so that the torso **110** seats in base groove **134**. Next, adjacently located pins **120** are seated. Cap **124** is then placed on pin housing base **122** to secure the pins **120** in position. Side walls **130** extend over the ends of the adjacent pins **120** and the sides of the pin housing base **122**. This process is repeated until each serpentine spring **104** is fitted with pins **120** secured in position by a pin housing **122**. The pins **120** and serpentine springs **104** are sized so that when the serpentine springs **104** are at rest (i.e., before expansion or compression) there exists some spacing in which the serpentine springs **104** can flex before the pins **120** stop further spring actuation.

Once pins **120** are seated within pin housing **122**, collimator **156** and light pipe **160** are seated within the inner hub **70** of diverter plate **56**. Collimator **156** is first seated on the step **84**. Light pipe **160** is next seated within groove **86**. Light pipe **160** is seated so that head **166** of light pipe **160** is spaced distally away from collimator **156**.

The printed circuit board **184** is seated within circular section **140**. The printed circuit board **184** is attached to circular section **140** using fasteners (not shown). Voltage regulator **186**, light sensitive transducer **158** and light source

15

154 are then seated on a distal face of the circular section 140. Voltage regulator 186 and light sensitive transducer 158 are located centrally on the circular section 140. Light sensitive transducer 158 is attached to the distal face of voltage regulator 186. Once these components are secured to the base plate 58, outer hub 72 is fastened and fixed to base plate 58.

Once diverter plate 56 is secured to base plate 58, head plate 54 is attached to inner hub 70. Specifically, threaded fasteners enter through first throughbores 62 and complimentary hub throughbores 80. This completes the assembly of force/torque sensor assembly 52.

As shown in FIG. 3, once force/torque sensor assembly 52 is assembled, the base plate 58 is mounted to the manipulator 30. Mounting plate 60 is then fixed to the head plate 54 and the instrument 32 is mounted onto the instrument mount 36.

VI. Other Embodiments

In some embodiments, the centroid coordinates can be utilized in an alternative manner to compute the forces and torques. The basic principle, however, remains the same, namely that movement of the centroids of the light beams on the light sensitive transducer 158 as loads are applied to the instrument 32 correlate to the six components of force and torque applied to the force/torque sensor assembly 52. One such embodiment is described below.

Referring to FIG. 17, as part of an initialization of manipulator 30, a memory integral with manipulator controller 48 is provided with data defining a distance R. The distance R is the distance from the center C of the force/torque sensor assembly 52 to the energy applicator 50. More specifically, the distance R is the distance from the center C of the force/torque sensor assembly 52 to the distal end tip of any tool or cutting accessory of the instrument 32. Here, the distal end tip is understood to be a bur of the energy applicator 50. For the bur, the distance R is the distance from the center C of force/torque sensor assembly 52 to the centroid 51 of the bur. Distance R can be determined using a navigation pointer (not illustrated) the position and orientation of which is tracked by the navigation system 220.

Manipulator controller 48 breaks down distance R into its x, y, and z-axis components, respectively, into distances r_x , r_y , and r_z . These distance components are stored in the memory. The above processes can be considered part of the step of providing and storing in the memory the sensor initial state data, step 260 of FIG. 18A.

The locations of the centroids of the light beams emitted through the normal bores 172, 174, 176, 178 when the force/torque sensor assembly 52 is in the unloaded state are represented as points 190, 192, 194, 196, respectively, in FIG. 14A. For reasons of simplicity, the points associated with the light beams that pass through angled bores 180, 182 are not shown in either FIG. 14A or FIG. 14B.

In a step 262 of FIG. 18A controller 48 determines the on-sensor unloaded state location of each light beam that extends through the normal bores 172, 174, 176, 178. Each of these locations is defined as a location ($STRX_m^U$, $STRY_m^U$). Through this document, superscript "U" represents the unloaded location of the variable. Subscript "m" identifies which one of the four light beams is specified.

Also, in step 262, controller 48 determines the on-sensor location of the light beams that extend through the individual angled bores 180, 182 when the force/torque sensor assembly 52 is in the unloaded state. These locations are the locations of the centroids of the light beams through the angled bores 180, 182, $ANGX_p^U$, $ANGY_p^U$. Subscript "p" identifies which one of the two light beams is specified.

16

In a step 264 of FIG. 18A, controller 48, calculates the distance between the on-sensor location between the two angled light beams, the distance between the two points $ANGX_p^U$, $ANGY_p^U$. This distance, depicted in FIG. 13A, is referred to as distance $ZADJ^U$.

The controller 48 assigns each light beam an initial start of frame location based on the location of the centroid of each light beam (initial centroid). For each light beam this is location ($STRX_m^S$, $STRY_m^S$). Here, superscript "S" represents the start of time frame location. For the first time frame, the start of frame location for each beam is set to the unloaded state on-sensor location of the light beam. In other words:

$$STRX_m^S = STRX_m^U \quad (1)$$

$$\text{and } STRY_m^S = STRY_m^U \quad (2)$$

Manipulator controller 48, in a step 266, calculates the slope of the line between the centroid locations of two of the light beams through the normal bores 172, 174, 176, 178. Often, the controller 48 determines the slopes of two lines that extend between centroid locations of the beams. Thus, the controller 48 determines the slope of lines 198 and 200 in FIG. 14A. Line 198 is the line between points 190 and 196, which identify the centroids of light beams through normal bores 172 and 178. Line 200 is the line between points 192 and 194 which identify the centroids of light beams through normal bores 174 and 176. Arbitrarily, slope S_1^S is the angle of the slope of line 198 and slope S_2^S is the angle of the slope of line 200. Slope is defined as the rise/run based on change in x/y from point 190 to point 196 in FIG. 14A.

Based on the signals from light sensitive transducer 158, controller 48 determines the end-of-frame on-sensor locations of the light beams, e.g., final centroid locations, in a step 268. As mentioned above, when the force/torque sensor assembly 52 is in the loaded state, the collimator 156 is in a shifted position relative to when in the unloaded state since the shifting of the inner hub 70 results of a like shifting of the position of the collimator 156. This means the light beams that pass through the collimator 156 strike different locations on the light sensitive transducer 158 than when the force/torque sensor assembly 52 is in the unloaded state.

In FIG. 14B, point 202 represents the shift of a centroid of a first beam from point 190. Point 204 represents the shift of a centroid of a second beam from the location of point 192. Point 206 represents the shift of a centroid of a third beam from the location of point 194. Point 208 represents the shift of a centroid of a fourth beam from the location of point 196.

Step 268 is performed using the same processes that are employed to perform step 262. Therefore, as a consequence of the execution of step 268, controller 48 has location data ($STRX_m^E$, $STRY_m^E$) for each of the four light beams associated with the normal bores 172, 174, 176, 178. In this document, superscript "E" indicates an end-of-frame location data or variable associated with the light beam or beams.

As a consequence of the collimator 156 shifting position, the on-sensor locations of the light beams that extends through the angled bores 180, 182 also shift position. The change in these positions is represented by the differences between FIGS. 13A and 13B. Therefore, as part of step 268, based on the end-of-frame signals from the light sensitive transducer 158, controller 48 determines the end-of-frame on-sensor location of the light beams that extend through each of the angled bores 180, 182. Each of these centroid locations is a point ($ANGX_p^E$, $ANGY_p^E$).

In a step 270, controller 48 determines the value of distance $ZADJ^E$ in the now loaded state. Step 270 is performed using the same processes that are employed to perform step 264. As

17

shown in FIG. 13B, distance $ZADJ^E$ is the distance between the on-sensor locations of the light beams that extend through angled bores **180**, **182**. In contrast to distance $ZADJ^U$, which is a constant, the value of distance $ZADJ^E$ is variable throughout the operation of force/torque sensor assembly **52**.

In a step **272**, controller **48** then calculates new slopes of the lines. With reference to FIG. 14B, this means the slope of line **210**, the shifted orientation of line **198** and the slope of line **212**, the shifted orientation of line **200** are calculated. Arbitrarily, slope S_1^E is the angle of the slope of line **210**; slope S_2^E is the angle of the slope of line **212**.

In a step **278**, manipulator controller **48** calculates the differences in on-sensor locations of the light beams through one of the angled bores **180**, **182**. These differences, $XSUP_p$ and $YSUP_p$, for the light beam, are the shifts along the x and y axes, of the location of the centroid of the light beam through the one of the angled bore **180**, **182** on light sensitive transducer **158** between the unloaded state position of the light beam and the end-of-frame position. Differences $XSUP_p$ and $YSUP_p$ are calculated according to the following formulas:

$$XSUP_p = ANG X_p^U - ANG X_p^E \quad (3)$$

$$YSUP_p = ANG Y_p^U - ANG Y_p^E \quad (4)$$

In a step **280**, manipulator controller **48** calculates a second set of differences representative in the shifts of the light beams that extend through normal bores **172**, **174**, **176**, **178**. These are differences in positions of the light beams (i.e., positions of centroids) between the start and end of the frame on-sensor beam locations. These differences are XSFR for the frame position shift along the x-axis and YSFR for the frame position shift along the y-axis. These differences are calculated according to the formulas:

$$XSFR_m = STRX_m^S - STRX_m^E \quad (5)$$

$$YSFR_m = STRY_m^S - STRY_m^E \quad (6)$$

Again, for the first frame of sensor operation, the unloaded state on-sensor locations ($STRX_m^U$, $STRY_m^U$) are employed as the minuends in Equations (5) and (6), respectively.

A further part of the shifted position calculations of step **280** is the calculation of the change in slope of at least one of the lines that extends between the on-sensor locations of light beams through the two of the normal bores **172**, **174**, **176**, **178**. This shift, SSFR, is unit less and is calculated according to the formula:

$$SSFR_n = S_n^S - S_n^E \quad (7)$$

Subscript "n" identifies which of the two lines the shift in angle is associated. As shown in FIGS. 14A and 14B, the slopes of lines **198** and **200** have shifted to the slopes of lines **210** and **212**, respectively.

Angle delta theta ($\Delta\theta$) is the measured angle shift between the slope of at least one of the lines measured from the initial frame and the end frame. Angle delta theta is measured in degrees.

$$\Delta\theta = \tan^{-1}(SSFR_n) \quad (8)$$

Controller **48** calculates location differences $XSUP_p$, $YSUP_p$, for the position shifts of the centroids of the light beams through the angled bores **180**, **182**. Location differences $XSFR_m$ and $YSFR_m$ are calculated for the shifts in position of the centroids of the light beams through the normal bores **172**, **174**, **176**, **178**. Also changes in slope SSFR_n is calculated. In one construction of the force/torque sensor assembly **52**, four light beams pass through the collimator **156** to the light sensitive transducer **158**. Specifically, these

18

four light beams are beams defined by both angled bores **180**, **182** and one pair of either set of opposed bores **172** and **178**, or **174** and **176**.

Manipulator controller **48**, based on the above differences in beam locations, inter-beam location distance ZADJ, and shifts in slope between the beam locations determines the forces and torques that are applied to the force/torque sensor assembly **52**.

In one embodiment, as illustrated in step **282**, based on differences $XSFR_m$ and $YSFR_m$ and the angle difference $SSFR_m$, the controller first determines torques T_x , T_y and T_z that are applied to the force/torque sensor assembly **52**. These three differences are a function of the torques applied to the force/torque sensor assembly **52**. More specifically, as previously described, it has been shown that T_x correlates to a shift in the centroids of the light beams along the y-axis and those shifts are indicated by $YSFR_m$. T_y correlates to a shift in the centroids of the light beams along the x-axis and those shifts are indicated by $XSFR_m$. T_z correlates to angle difference $SSFR_m$.

Controller **48** executes step **282** by applying the set of these differences as input values into a torque look-up table to which the controller has access. Each set of these three differences corresponds to a set of torques T_x , T_y and T_z stored in the table. The torques may also be determined using the linear algebra methods described above based on a multiple linear regression model. The torques from the look-up table or multiple linear regression model are then used to calculate the forces applied to the instrument **32**. More specifically, the forces applied to the instrument **32** that yield these torques are determined based on the well known relationship $T = F * r * \sin \theta$. These forces can then be translated to the coordinate system of the force/torque sensor assembly **52** since the instrument **32** is considered to be part of the same rigid body as the inner hub **70** of the force/torque sensor assembly **52**. The relationship between the forces and torques is such that when forces are applied along the x, y, or z axes, a torque is always generated at the force/torque sensor assembly **52** given the configuration of the instrument **32** and its spatial relationship to the force/torque sensor assembly **52**. Sample calculations for the forces in one embodiment are shown below.

In a step **284** controller **48** first calculates the force F_z . Force F_z is determined as a function of torque T_z , the position of the instrument **32** relative to the force/torque sensor assembly **52**, and Delta angle theta:

$$F_z = \frac{T_z}{r_z \sin(\Delta\theta)} \quad (9)$$

Here, distance r_z is the z-axis component of vector \vec{R} . Delta angle theta ($\Delta\theta$) is the measured angle shift between at least one of the measured lines, as previously described. Delta angle theta is determined using Equation (8).

In a step **288**, the force F_x is calculated. This force is determined by initially calculating an angle Ψ_x , an x-axis collimator deflection angle. Deflection angle Ψ_x is the angular rotation about the x-axis of the collimator **156** from when the force/torque sensor assembly **52** is in the unloaded state to the end-of-frame state. This is the rotation of the x-axis in the y-z plane. In a step **286**, deflection angle Ψ_x is determined according to the formula:

$$\Psi_x = \tan^{-1} \frac{ZADJ_m^U + \left[\frac{ZADJ_m^U - ZADJ_m^E}{2} \right]}{XSUP_p} \quad (10)$$

Owing to the shift of the collimator **156** along substantially the z-axis, $ZADJ^E$ is a variable that is measured after every frame of force/torque sensor assembly **52** operation. Once deflection angle Ψ_x is calculated, force F_x is determined in step **288** according to the following formula:

$$F_x = \frac{T_x}{r_x \sin(\Psi_x)} \quad (11)$$

In a step **292** the force F_y is calculated. This force is determined by initially determining deflection angle Ψ_y , a y-axis collimator deflection angle. Deflection angle Ψ_y is the angular rotation about the y-axis of the collimator **156** from when the force/torque sensor assembly **52** is in the unloaded state to the end-of-frame state. This is the rotation of the y-axis in the x-z plane. In a step **290**, deflection angle Ψ_y is determined according to the formula:

$$\Psi_y = \tan^{-1} \frac{ZADJ_m^U + \left[\frac{ZADJ_m^U - ZADJ_m^E}{2} \right]}{YSUP_p} \quad (12)$$

$ZADJ^E$ is the same value determined by controller **124** in step **286**. Here, $YSUP_p$ is the shift along the y-axis of the location of a light beam through a single angled bore **180**, **182** on light sensitive transducer **158** between the unloaded position and end-of-frame position. Once Ψ_y is calculated, force F_y is determined according to the following formula:

$$F_y = \frac{T_y}{r_y \sin(\Psi_y)} \quad (13)$$

Thus, upon execution of step **292**, controller **124** has determined six variables, the three torques T_x , T_y , and T_z , and the three forces F_x , F_y , and F_z , applied to the force/torque sensor assembly **52**. The force and torque data are then forwarded to other modules integral with the manipulator controller **48**, step not shown. These other modules employ the force and torque data to regulate the operation of the manipulator **30**.

In a step **300**, controller **48** then defines the start-of-frame light beam locations for the next time frame. These are the start of frame locations $XSUP$, $YSUP$ for the light beams through two of the normal bores **172**, **174**, **176**, **178**. In step **300**, end-of-frame on-sensor light beam locations ($STRX$, $STRY$) of each normal bore light beam for the current frame become the new start-of-frame locations ($STRX$, $STRY$) for the next frame.

In a step **302**, end-of-frame inter-beam slopes are set to define a next frame start-of-frame inter-beam slope. Controller **48** then proceeds to reexecute step **268**, to determine the end-of-frame light beam locations for the next frame, now the current frame. Once step **268** is reexecuted the steps following step **268** are also reexecuted. Controller **48** thus continually outputs the data describing in essentially real time the forces and torques that are applied to the force/torque sensor assembly.

In some embodiments, the locations of the light beams for the normal bores **172**, **174**, **176**, **178** and angled bores **180**, **182** in the loaded state, for each frame, are compared to their locations in the unloaded state to determine forces and torques, as opposed to being compared to their locations at the end of the last time frame. Thus, the start-of-frame locations of the light beams for each computation are the locations of the light beams in the unloaded state with all determinations of forces and torques during operation being considered from the unloaded state to determine total forces and torques applied relative to the unloaded state as opposed to measuring incremental forces and torques applied in each time frame.

In other embodiments, a torque sensor assembly is provided where, based on differences $XSFR_m$ and $YSFR_m$, and the angle difference $SSFR_m$, the controller only determines torques T_x , T_y , and T_z that are applied to the torque sensor assembly wherein the torque sensor assembly has the same features as the force/torque sensor assembly **52** with the only difference being that only torques are measured.

FIGS. **20** and **21** depict an alternative collimator **156A** with multiple sets of angled bores **180A**, **182A**.

FIGS. **22-24** depict alternative embodiments of the diverter plate **56**. These alternative diverter plates are substantially the same as diverter plate **56**, but with different spring arrangements. For example, in FIG. **22**, the serpentine springs **104A** have been rotated ninety degrees. As a result, the inner hub **70A** is movably coupled to the outer hub **72A** by three spring devices **102A** including three serpentine springs **104A** and three leaf springs **106A**. Pins **120A** are also positioned to act as stops for the serpentine springs **104A**.

In FIG. **23**, three spring devices **120B** are shown that include leaf springs **106B** similar to the leaf springs **106**, but the serpentine springs **104** have been replaced with cylindrical hollow resilient members surrounding elongated pins **120B** that act as stops for the cylindrical hollow resilient members. In this embodiment, the first stage of spring displacement is to compress the cylindrical hollow resilient member against the pin **120B**. This stops the first stage and then the second stage continues by flexing the leaf spring **106C**. Thus, the leaf spring **106C** is configured to have a spring rate that prevents substantially flexing until the first stage is complete.

In FIG. **24**, three spring devices **120C** are shown that include leaf springs **106C** similar to the leaf springs **106**, but the serpentine springs **104** have been replaced with two cylindrical hollow resilient members arranged in series. Elongated pins **120C** act as stops for these cylindrical hollow resilient members.

In some embodiments, structural members other than the disclosed diverter plate may serve as the transducer that, in response to the application of force and torque, selectively direct the light emitted towards the light sensitive transducer **158**. In other words, structural sensor members other than the inner hub **70** may move relative to the base plate **58** to selectively direct the light emitted towards the light sensitive transducer **158**.

The tines **78** may number less than three or more than three. In other versions, tines **78** may be dimensioned to inhibit unnecessary flexure of the inner hub **70** within the force/torque sensor assembly **52**.

In some embodiments, the force/torque sensor assembly **52** is part of the manipulator **30**. In other embodiments, the force/torque sensor assembly **52** is a separate assembly acting between the manipulator **30** and the instrument **32**.

In some embodiments, the outer hub **72** is fixed directly to the distal end component **138** of the linkage assembly **40** and acts as the base plate for the force/torque sensor assembly. In

21

this embodiment, the light sensitive transducer **158** may be recessed in a pocket in the distal end component **138** of the linkage assembly **40**.

In some embodiments, collimator is square in shape. In these embodiments, inner hub bore **80** is configured to be square in shape so that a square-shaped collimator may seat within inner hub.

In some embodiments, the abutment of folds **114** against the pins **120** prevents plastic deformation of the pleats **116**. Consequently when forces and/or torques are removed and then new forces and/or torques applied, the serpentine springs **104** will again undergo expansion or compression that is linearly related to the magnitude of the applied forces and torques in the first or second stage of spring displacement.

Several embodiments have been discussed in the foregoing description. However, the embodiments discussed herein are not intended to be exhaustive or limit the invention to any particular form. The terminology which has been used is intended to be in the nature of words of description rather than of limitation. Many modifications and variations are possible in light of the above teachings and the invention may be practiced otherwise than as specifically described.

What is claimed is:

1. A sensor assembly comprising:
 - a base plate;
 - a sensor member displaceable relative to said base plate;
 - a spring arrangement having first and second stages reactive to displacement of said sensor member relative to said base plate with different resolutions of force and torque measurements being associated with said first and second stages, wherein said spring arrangement is configured to transition to said second stage after said first stage; and
 - a light sensitive transducer for sensing displacement of said sensor member relative to said base plate and for generating corresponding output signals.
2. The sensor assembly of claim 1 wherein said spring arrangement includes:
 - a plurality of first springs reactive to displacement of said sensor member relative to said base plate, each of said first springs being displaceable in said first stage and having a first spring rate; and
 - a plurality of second springs reactive to displacement of said sensor member relative to said base plate, each of said second springs being displaceable in said second stage and having a second spring rate different than said first spring rate.
3. The sensor assembly of claim 2 wherein said first springs are leaf springs.

22

4. The sensor assembly of claim 3 wherein said second springs are serpentine springs.

5. The sensor assembly of claim 4 wherein each of said serpentine springs has a first end connected to said sensor member and a second end connected to one of said leaf springs.

6. The sensor assembly of claim 4 wherein each of said serpentine springs includes a head, a torso, and a leg.

7. The sensor assembly of claim 6 wherein said torso includes a U-shaped fold.

8. The sensor assembly of claim 7 wherein each of said leaf springs has feet extending in opposing directions from one of said legs of said serpentine springs.

9. The sensor assembly of claim 7 including a plurality of pins for interacting with said serpentine springs.

10. The sensor assembly of claim 9 wherein said plurality of pins includes a first pin positioned between said head and said torso, a second pin positioned in said U-shaped fold, and a third pin positioned between said torso and said leg.

11. The sensor assembly of claim 10 including a pin housing securing said first, second, and third pins in position.

12. The sensor assembly of claim 11 wherein said pin housing includes a pin housing base and a cover disposed over said pin housing base, said first, second, and third pins secured between said cover and said pin housing base.

13. The sensor assembly of claim 1 including an outer hub fixed to said base plate.

14. The sensor assembly of claim 13 wherein said sensor member is further defined as an inner hub, said spring arrangement acting between said inner hub and said outer hub.

15. The sensor assembly of claim 14 including a head plate fixed to said inner hub, said head plate configured to be coupled to an instrument and said base plate configured to be coupled to a linkage assembly.

16. The sensor assembly of claim 14 including a plurality of tines extending radially outwardly from said inner hub.

17. The sensor assembly of claim 16 wherein said outer hub defines a plurality of slots for receiving said tines wherein each of said slots are dimensioned to allow movement of said tines in said slots.

18. The sensor assembly of claim 1 including a light source and a collimator for directing light from said light source onto said light sensitive transducer.

19. The sensor assembly of claim 1 including a stop configured to interact with said spring arrangement to transition said spring arrangement from said first stage to said second stage.
